Subsurface stratigraphy of the Morrison Formation in the Mount Taylor area and its relation to uranium ore genesis

Walter C. Riese and D. G. Brookins, 1977, pp. 271-275

in:

This is one of many related papers that were included in the 1977 NMGS Fall Field Conference Guidebook.

Annual NMGS Fall Field Conference Guidebooks

Every fall since 1950, the New Mexico Geological Society (NMGS) has held an annual Fall Field Conference that explores some region of New Mexico (or surrounding states). Always well attended, these conferences provide a guidebook to participants. Besides detailed road logs, the guidebooks contain many well written, edited, and peer-reviewed geoscience papers. These books have set the national standard for geologic guidebooks and are an essential geologic reference for anyone working in or around New Mexico.

Free Downloads

NMGS has decided to make peer-reviewed papers from our Fall Field Conference guidebooks available for free download. Non-members will have access to guidebook papers two years after publication. Members have access to all papers. This is in keeping with our mission of promoting interest, research, and cooperation regarding geology in New Mexico. However, guidebook sales represent a significant proportion of our operating budget. Therefore, only research papers are available for download. Road logs, mini-papers, maps, stratigraphic charts, and other selected content are available only in the printed guidebooks.

Copyright Information

Publications of the New Mexico Geological Society, printed and electronic, are protected by the copyright laws of the United States. No material from the NMGS website, or printed and electronic publications, may be reprinted or redistributed without NMGS permission. Contact us for permission to reprint portions of any of our publications.

One printed copy of any materials from the NMGS website or our print and electronic publications may be made for individual use without our permission. Teachers and students may make unlimited copies for educational use. Any other use of these materials requires explicit permission.

SUBSURFACE STRATIGRAPHY OF THE MORRISON FORMATION IN THE MOUNT TAYLOR AREA AND ITS RELATION TO URANIUM ORE GENESIS

WALTER C. RIESE
Gulf Mineral Resources Company
Albuquerque, New Mexico

and

DOUGLAS G. BROOKINS
Department of Geology
University of New Mexico
Albuquerque, New Mexico

INTRODUCTION
This article is an outgrowth of a subsurface stratigraphic study of the Morrison Formation present near San Mateo, New Mexico, on properties being explored and developed by Gulf Mineral Resources Company (fig. 1). This project was undertaken as part of a M.S. thesis project for the University of New Mexico. The principal aim of this study has been to carry out detailed stratigraphic correlation through the use of electric logs, core analysis and thin section analysis in order to define the paleoenvironments of the Jurassic Morrison Formation in the Ambrosia Lake and Mount Taylor areas and to determine what roles these environments have played in uranium ore genesis.

STRATIGRAPHY OF THE HOST ROCKS
General Background
Sandstone-type uranium deposits in the United States occur in about 140 stratigraphic units representing nearly every period in the geologic record (Fince, 1967). Of these, the most prolific producers were deposited in fluvial environments.

The deposits of the Grants mineral belt and Mount Taylor are found in the Late Jurassic Morrison Formation, which is composed of fluvial sandstone lenses that are interbedded with mudstone (Cadigan, 1959; Santos, 1970). Many of the sandstone beds are arkosic, and some of the mudstone beds contain clay minerals derived from volcanic ash. The streams that deposited the host sandstones are generally assumed to have flowed to the east and northeast from the ancestral Mogollon highland into a depositional basin (Cadigan, 1959; Santos, 1970; Flesch, 1974a).

Morrison Formation
The Morrison Formation was named by Cross (1894) for exposures near the town of Morrison in east-central Colorado. It has been recognized over most of the western interior of the United States, and its age, relationships and correlation have been the object of considerable discussion. A summary of the development of Morrison nomenclature is offered by Imlay (1952), Flesch (1974a) and Sears and others (1974).

Much of the present study has been devoted to a subsurface analysis of the geometrics and lithologies of the Morrison in the Mount Taylor area. This was carried out by the analysis of detailed core descriptions, thin section studies and geometric analysis through cross-sectioning of the lithosomes that constitute the Morrison Formation. Data for this cross-sectional analysis were gathered from a suite of electric logs that measured gamma-ray, self-potential and resistivity characteristics of Morrison stratigraphy. Where logs of deviated or whipstocked holes were used, measured formation thicknesses were trigonmetrically corrected to true formation thicknesses. The Morrison is divided into three mappable members in the Mount Taylor area. From oldest to youngest these are the Recapture, Westwater Canyon and Brushy Basin members. On the basis of lithology, fossils and geometry, the members are interpreted as fluvial and all intertongue (fig. 2) with overlying and underlying units. Therefore, the contacts delimiting the stratigraphic range of each member are arbitrary (Harshbarger and others, 1957), but lithologic differences and weathering properties provide a basis for their differentiation.
The Westwater Canyon Member is composed of complexly interbedded pebble conglomerates, sandstones, and mudstones. These lithologies are variously colored throughout the section in shades of gray, black, and green to grayish yellow. The sands constitute by far the greatest portion of the section; 70-80 percent of the sands consist of subangular to rounded quartz. Orthoclase, plagioclase feldspar and lithic fragments make up the remainder. The silts and pebble conglomerates are similarly composed, but the mudstones are locally made up almost entirely of clay minerals.

In the Mount Taylor area, the Westwater Canyon Member exhibits a characteristic shaly bed that is referred to as the "K" shale in the Grants mineral belt (fig. 2). It is present throughout the area of study and apparently prohibits any connection of the lower Westwater Canyon lithosome (Jmwc) with the upper Westwater Canyon lithosome (Jmuwc). It is identical in appearance to the Brushy Basin Member and may correlate with the "shale" between the "b" and "c" sands (local usage) of the Ambrosia Lake district.

The Westwater Canyon Member intertongues with, grades into, and unconformably adjoins both the underlying Recapture and the overlying Brushy Basin members throughout the southern San Juan Basin. These relations are all expressed in the subsurface geometry of the Mount Taylor area as well.

Brushy Basin Member

The Brushy Basin Member is the uppermost member of the Morrison Formation (Gregory, 1938). In the Grants mineral belt it is composed of a sequence of fine- to very fine-grained sands, siltstones and mudstones which grade into one another, although disconformities are locally distinguishable. Colors range from shades of gray and green to grayish brown. The mudstones and siltstones constitute the greatest part of the section, although sands very similar to those attributed to the Westwater Canyon may also be found in the sequences.

The Brushy Basin Member intertongues with, grades into, and unconformably adjoins both the underlying Recapture and the overlying Brushy Basin Member. Its contact with the overlying Dakota Sandstone (Cretaceous) is a well-documented unconformity in the Mount Taylor area and over most of the Colorado Plateau as well (Gregory, 1938; Harshbarger and others, 1957; Peterson, 1972).

Depositional Environments of the Morrison Formation

The depositional environments of the Morrison Formation have been outlined by many of the authors already cited. Hilpert (1963, p. 14) had an excellent summary of the views held by many working in the district:

"Studies of the lithologies and sedimentary structures of the Morrison by Craig et al. (1955) indicate that the sediments were largely derived from a landmass in east-central Arizona and west-central New Mexico and were deposited by an aggrading system of north-eastward flowing streams. The sediments of the Brushy Basin Member were probably deposited in a mixed lacustrine and fluvial environment in which the fluvial material probably came largely from the Mogollon Highland to the south (Harshbarger et al., 1957). The bentonitic claystone is interpreted to be a derivative of volcanic ash." (Craig et al., 1955).

These conclusions were previously stated by Silver (1948) and have been more recently expounded by Peterson (1972, p. 186):

"The continental beds of the Morrison Formation were deposited essentially as a region-wide blanket of variable lithology on the sea floor plain which emerged after the final marine Jurassic cycle of deposition" (Swift).

Flesch (1974a) also agreed with these findings but indicated
SUBSURFACE STRATIGRAPHY
the need for caution pending correlation of the extensive out-
crop studies with subsurface studies.

Figure 2 is a generalization of a large number of cross sec-
tions constructed through the study area. Note the distinct
lens-like development in the upper Westwater Canyon sands
(Jmuwc), which in an isometric diagram might look very
similar to the meander-belt deposits illustrated in Figure 3.
The Morrison Formation, specifically the Westwater Canyon
Member, was probably not deposited as a purely meandering
stream belt; the specific fluvial environments of deposition of
the various Morrison lithosomes were discussed by Flesch
(1974b) in a detailed fashion that cannot be duplicated here
because of a lack of samples. Nor is the sand thick depicted in
Figure 2 representative of the filling of a single mega-channel.
This would be unlikely. This sand thick probably represents a
lithosome that was deposited by a succession of streams during
the course of Morrison deposition. The lithosomes on either
side represent areas that were flood plains during this same
time.

Constraints on the lateral development of this stream
system were probably imposed by small-scale topographic
relief present in the area during Morrison deposition. This
relief may have been nothing more significant than that which
bounds the present-day Rio Salado of west-central New
Mexico along much of its length.

Alternately, it may have owed its development to structural
flexing during continued subsidence of the San Juan Basin
(Saucier, 1975). Because the contact of the Westwater Canyon
and Recapture members shows no structural distortion, we
feel that this topography is probably due to normal geo-
morphic development of the area and not to structural flexing.

Further evidence for the presence of this paleotopography is
found in the variations in thickness of the section bounded by
the top of the "K" shale and the top of the Brushy Basin
Member. Recognizing that this last contact is unconformable,
but assuming for the sake of argument that this surface is
planar and parallel to the underlying stratigraphy, the de-
signated stratigraphic section thins laterally away from the
thicks in the sand bodies, thus delimiting the valley of interest,
and then locally begins to thicken again to the north, sug-
gest that a second valley parallels the one which is illus-
trated in this section.

Morrison deposition, at least in the Mount Taylor area, is
not simply a collection of northeasterly coalescing streams and
alluvial fans. Rather, this pattern was broken by the south-
easterly flowing channel system just described. This channel
system was fed by the northeasterly and easterly flowing
streams whose directions of flow are so well documented in
the already mentioned outcrop studies. This stream system
could not have reached the base level offered by the sea if its
course had continued to the southeast, because the Jurassic
seas of Swift age had transgressed the western interior of the
United States from the north (Peterson, 1972). This stream
must therefore have eventually turned north, probably in the
area of the Laguna-Paguate district, as indicated by the greater
than 50 percent sand lithofacies bulge present in north-central
New Mexico (Peterson, 1972, fig. 8).

STRATIGRAPHIC ORE CONTROLS
The uranium deposits in the Ambrosia Lake and Mount
Taylor areas have for many years been recognized as associated
with the fluvial paleoenvironments preserved in the Jurassic
Morrison Formation. These relationships have been sum-
marized very well by Fischer (1974). The environments of
deposition and mineralization visualized by Fischer (1974),
and by most workers in the district, involve a system of
generally northeasterly flowing streams that drained a highland
to the southwest. The uranium was provided by leaching of
source rocks in the provenance and depositional areas—either
granitic intrusive materials that were being unroofed at the
time of deposition and which provided much of the uranium
material deposited in the Westwater Member of the Morrison,
or tuffaceous volcanic material in the overlying and inter-
figering Brushy Basin Member. The leaching solutions then

Figure 3. Idealized alluvial sand patterns (from Pettijohn and others, 1973).
moved down dip to areas with chemically reducing environments, where the uranium was then reduced and precipitated from solution, usually in and owing to local accumulations of carbonaceous material.

This concept of depositional and mineralization environments fails to explain the elongate southeast-northwest nature of the deposits; one normally might expect a Uravan-type of distribution (C. T. Smith, personal communication) with the ore bodies parallel to the stream-flow directions, in this case a northeasterly direction.

In Figure 2, the upper Westwater Canyon has been noted to have a crudely lenticular outline, which is locally quite thick in the center and diminishes in thickness to the north and south as the member lenses out and interferes with the mudstones and siltstones of the Brushy Basin. We believe that this stratigraphic geometry does not represent a system of northeasterly flowing streams, but rather a southeasterly trending valley. Through this valley flowed a complex system of braided and meandering streams, which through time deposited a sand lithosome similar in cross-sectional appearance to a single stream deposit.

A second significant characteristic of the Ambrosia Lake area is the repetition of ore deposits in a direction parallel to the strike of the structure in the area—northwest-southeast. This distribution is also present in the Mount Taylor area and is interpreted to represent frequency of meander in the stream system just described. More specifically, a series of point bar deposits would account for the distribution noted. These areas are places where the sands of the Westwater Canyon inter-tongue most freely with the muds of the Brushy Basin. Where these muds contain high concentrations of clay minerals, these too may serve as collecting sites for the uranium. This tendency is best shown in what are interpreted to be shale lenses in the centers of channels. These areas are often barren of any carbonaceous materials that could have aided precipitation, and therefore the uranium found here is present solely through precipitation by clay minerals.

Although the Brushy Basin Member of the Morrison Formation is not composed entirely of clay minerals, but rather of clay size materials, there are sufficient clay minerals in the member to have effectively sealed it with respect to fluvial migration early in the diagenetic process. Hostetler and Garrels (1962) considered the tuffaceous materials in the Brushy Basin to be the source of the uranium in the deposits and suggested that this material was leached very soon after deposition and moved into more permeable materials. Their model requires that the leach solutions be squeezed from the enveloping mudstones into permeable sand channels along which they could then migrate to locations of precipitation and concentration.

A diagrammatic representation of the distribution of anomalous background values of the gamma radiation in the Morrison is superimposed on the stratigraphy in Figure 2. Notice the resemblance to a C-shaped roll and how this roll transgresses lithologic boundaries. This distribution, as well as the thorium trace element geochemical data discussed in another paper in this volume, suggests a model that uses the host formations as source rocks for the uranium as well. Leaching took place during deposition and early diagenesis. As compaction began, these leach solutions were squeezed from the muds and migrated down dip as the mega-roll we see frozen in this figure. As compaction continued, the mudstones lost most of their permeability; but the stream channels, which were filled with sands, remained relatively open and permeable and allowed ore material to accumulate.

CONCLUSIONS

The principal aim of this study has been to carry out detailed stratigraphic correlation through the use of electric logs, core analysis and thin section analysis in order to define the paleoenvironments of the Jurassic Morrison Formation in the Ambrosia Lake and Mount Taylor areas and to determine what roles these environments have played in uranium ore genesis. With regard to the environments, this study shows that the Morrison streams of Westwater time drained to the southeast and not to the northeast as suggested by previous workers. We suggest that this interpretation was not made earlier because the subsurface data base used in this study was not available.

The ore deposits in the Mount Taylor area are preferentially located with respect to point bar deposits in the fluvial systems of the Westwater Canyon Member. Both carbonaceous materials and clay minerals appear to have had some role in precipitation. The interaction between the two remains a question to be answered by future research in the area.

ACKNOWLEDGEMENTS

We wish to acknowledge the encouragement and many useful suggestions offered by the staffs of Gulf Mineral Resources Company and Gulf Science and Technology Company. Special acknowledgement is made of the generosity shown by the management of Gulf, who allowed the use of many feet of core samples, numerous electric logs and extensive laboratory facilities. Without that help this project could not have been completed.

We wish to thank the New Mexico Geological Society for a grant made to help defray the cost of thin section preparation.
