---

This is one of many related papers that were included in the 1979 NMGS Fall Field Conference Guidebook.

### Annual NMGS Fall Field Conference Guidebooks

Every fall since 1950, the New Mexico Geological Society (NMGS) has held an annual Fall Field Conference that explores some region of New Mexico (or surrounding states). Always well attended, these conferences provide a guidebook to participants. Besides detailed road logs, the guidebooks contain many well written, edited, and peer-reviewed geoscience papers. These books have set the national standard for geologic guidebooks and are an essential geologic reference for anyone working in or around New Mexico.

### Free Downloads

NMGS has decided to make peer-reviewed papers from our Fall Field Conference guidebooks available for free download. This is in keeping with our mission of promoting interest, research, and cooperation regarding geology in New Mexico. However, guidebook sales represent a significant proportion of our operating budget. Therefore, only research papers are available for download. Road logs, mini-papers, and other selected content are available only in print for recent guidebooks.

### Copyright Information

Publications of the New Mexico Geological Society, printed and electronic, are protected by the copyright laws of the United States. No material from the NMGS website, or printed and electronic publications, may be reprinted or redistributed without NMGS permission. Contact us for permission to reprint portions of any of our publications.

One printed copy of any materials from the NMGS website or our print and electronic publications may be made for individual use without our permission. Teachers and students may make unlimited copies for educational use. Any other use of these materials requires explicit permission.

INTRODUCTION
The Embudo Granite is located in north-central New Mexico in the Picuris Range of the southern Sangre de Cristo Mountains. Montgomery (1953) applied the term "Embudo" to all the Precambrian granitic rocks exposed between the Picuris Range and Santa Fe, about 48 km to the south. Samples analyzed in this study were collected from the area mapped by Montgomery (Miller and others, 1963) and Long (1974) (fig. 1).

The purpose of this study was to add to the framework for studies in the Picuris Range by: (1) determining the crystallization sequence of the Embudo Granite and (2) analyzing for rare-earth and other trace elements of two of the subunits of the Embudo Granite.

GEOLOGY AND PETROGRAPHY
The Precambrian rocks in the Sangre de Cristo Mountains consist of metasedimentary and metavolcanic rocks and the intrusive Embudo Granite. The Embudo Granite intrudes all Precambrian rocks in the area, namely the Ortega Formation, including the Rinconada and Pilar Members, and the Vadito Formation.

The granitic rocks in the northern part of the area may be divided into four distinct units. According to Long (1974), the sequence of granitic magmatism began with the emplacement of a dark to medium gray, fine-grained metadacite stock (Cerro Alto metadacite), along with sills and dikes of similar lithology. This event was followed by the emplacement of a more coarse-grained and foliated granite-quartz-monzonite porphyry with distinctive phenocrysts of microcline (Puntiagudo granite porphyry) (see Long and Luth, this guidebook). This rock was intruded by a foliated biotite quartz monzonite (Rana quartz monzonite), followed by the intrusion of the Pefiasco quartz monzonite. The granitic rocks in the southern part of the area of study have not been subdivided into distinctive units, and it is unknown whether the two bodies are related genetically.

PREVIOUS AGE DETERMINATIONS
Muehlberger and others (1966) summarized Precambrian ages for metamorphic and igneous events in north-central New Mexico and south-central Colorado. They recognized four Precambrian thermal events in New Mexico, primarily on the basis of Rb-Sr whole-rock and mineral ages. Using a 47 b.y. half-life for $^{87}$Rb, the recognized events occurred about 1600, between 1430 and 1350, at 1280 and at 1100 m.y.

A K-Ar age of 1,235 ± 19 m.y. for biotite from the Embudo Granite was obtained by Gresens (1972), and Fullagar and Shiver (1973) found by Rb-Sr dating that the most likely age of formation for the Embudo Granite was 1,673 ± 41 m.y.
Long L i/f) sunaiviaeu tne granite arm reinterpreteu I umtgaig and Shiver's data to obtain separate ages for the subunits, ranging from 1673 to 1400 my.

ANALYTICAL PROCEDURES AND RESULTS

From the northern part of the study area, six samples from the Puntiagudo granite porphyry and five from the Rana quartz monzongite were analyzed for major elements, Rb and Sr concentrations, and rare-earth and other trace-element data (Register, 1979). From the southern part of the study area, eight samples of the Embudo Granite (undivided) were analyzed for Rb and Sr concentrations and Sr isotopic ratios by P. D. Fullagar (personal commun., 1978).

Major-element analyses (Table 1) were carried out by atomic absorption spectrophotometry and other standard wet-chemical analytical techniques.

Rb and Sr concentrations and Sr isotopic compositions (Table 2) were determined by mass spectrometric techniques. Rb and Sr concentrations were determined by standard isotope-dilution techniques using 87Rb and 84Sr spikes. The 85Rb/87Rb ratio was taken to be 2.591, and the decay constant for 87Rb was taken as 1.42 x

Analyses of Eimer and Amend standard SrCO3 give an average normalized 87Sr/86Sr ratio of 0.7080 with a standard deviation of 0.0003. All Rb-Sr ages and initial 87Sr/86Sr ratios have been calculated using the least-squares cubic-regression method of York (1969). One-standard-deviation experimental errors of 0.05 percent and 1 percent have been assigned to the (87Sr/86Sr)N and 87Rb/86Sr, respectively.

Samples from the northern part of the study area were analyzed for rare-earth and other trace elements by instrumental neutron activation analysis (INAA); data are presented in Register (1979). The uranium content for each sample was determined by delayed neutron activation analysis (DNAA). Both INAA and DNAA were carried out at the Los Alamos Scientific Laboratory (LASL) using their 8MW Omega West Reactor as a neutron source. Procedures for analyses are similar to those described by Della Valle and Brookins (in press).

DISCUSSION

The linear fit to the Rb-Sr data for whole rocks from the Puntiagudo granite porphyry (fig. 2a) yields an age of 1,547 ± 138 m.y. and an initial 87Sr/86Sr ratio of 0.7056 ± 0.0053 (1a). This age is younger than that reported by Fullagar and Shiver (1973) for all units of the Embudo Granite, and Long's (1974) reinterpretation of those data, unless a maximum error is used.

The low 87Sr/86Sr initial ratio of the Puntiagudo granite porphyry implies that the original magma, from which the granitic magma fractionated, may have originated in the lower
crust from material not long removed from a low 87 Sr/86 Sr source. The granitic magma incorporated little radiogenic Sr from old crustal rocks, as evidenced by the low initial ratio.

The linear fit to the Rb-Sr data for whole rocks from the Rana quartz monzonite (fig. 2b) yields an age of 1,441 ± 157 m.y. and an initial ratio of 0.7113 ± 0.0071. This age is also younger than that suggested by Long (1974); however, the slope is extremely dependent on sample Rqm-1, and any slight variation in this point would cause changes in slope, and thus, the age.

The apparently high 87Sr/86Sr initial ratio of the Rana quartz monzonite is puzzling, especially when one considers that most of the points from Fullagar and Shiver (1973), which yield an initial ratio of 0.7012, are probably samples from the Rana quartz monzonite. The dependence of the slope of Rqm-1 could be a possible explanation of this high ratio. This particular sample is highly foliated, and if the post-tectonic metamorphic event or one of the two subsequent thermal events (reported by Nielsen and Dunn (1974) and confirmed by Holdaway (1978)) were accompanied by local metasomatism in the quartz monzonite, this could result in an apparent lowering of that point, resulting in a higher initial ratio.

The linear fit to the Rb-Sr data for eight whole-rock samples from the Embudo Granite in the southern part of the study area (fig. 3) yields an age of 1,464 ± 50 m.y. (very close to the age obtained for the Rana quartz monzonite to the north), and an initial ratio of 0.7044 ± 0.0042. It is unknown whether these rocks are related genetically; however, they are related temporally and spatially. These ages fall within the 1,430-to-1,350 m.y. event reported by Muehlberger and others (1966) (when using 1.42 x 10-11y-1 as the decay constant as opposed to 1.47 x 10-11y-1).

Chemical differentiation trends (Register, 1979) for the whole rocks from the northern part of the study area are the same as those reported for the Embudo Granite (undivided) by Fullagar and Shiver (1973), suggesting that the analyzed rocks are comagmatic.

Trace elements in both the Puntiagudo granite porphyry and the Rana quartz monzonite fall within the same range of reported concentrations of other granitic rocks. Both show similar REE concentrations to those reported for a composite granite with more than 70% SiO2 (Haskin and Frey, 1966). The rare-earth patterns for both suites (figs. 4a, 4b) show typical granitic trends with relative enrichment in the light rare-earths (La to Sm) and depletion in the heavy rare-earths. Slight negative cerium and europium anomalies are observed in both groups, which is also typical for most granites, due, presumably, to oxidation effects.

CONCLUSIONS

The results of this study support the following conclusions:

(1) The Puntiagudo granite porphyry and the Rana quartz monzonite were intruded at 1,547 ± 138 m.y. and 1,441 ± 157 m.y., respectively.

(2) The Embudo Granite (undivided) to the south yields an age of 1,465 ± 50 m.y., contemporaneous with the Rana quartz monzonite.

(3) The granites in the northern part of the area are probably comagmatic with those analyzed by Fullagar and Shiver (1973) to which they are spatially related.

(4) Typical granitic REE and other trace-element distributions are seen for the Puntiagudo granite porphyry and the Rana quartz monzonite.
